

THE TOPOLOGY OF ALGEBRAIC MANIFOLDS

THOMAS BRAZELTON

ABSTRACT. Course notes from MATH231b: algebraic topology II, taught at Harvard in Spring 2026.

<https://github.com/tbrazel/math231br>

0. ABOUT

These notes are from a MATH213BR, a second-semester graduate algebraic topology class with a free-floating curriculum taught at Harvard in spring of 2026. This particular course is modeled off of Hirzebruch's amazing 1962 text *Neue topologische Methoden in der algebraischen Geometrie*. Theorem counters and page references refer to the 1995 reprinting in English [Hir78].

0.1. Overview. Part 1: We begin with the theory of sheaves of sets and discrete groups on topological spaces, developing their cohomology and comparing it with singular and de Rham cohomology. We continue with sheaves of topological groups (aka fiber bundles) and develop their basic theory. We then discuss vector bundle theory and Chern and Pontryagin classes.

Part 2: We develop the ideas of oriented cobordism and basic index theory.

0.2. References. Aside from the main text, which we deviate from at various points, some other references which have informed the presentation here include:

- ▷ *sheaf theory*: Godement's original work [God58], and of course Serre's [Ser55]
- ▷ *fiber bundles*: Steenrod's 1951 printing [Ste51]
- ▷ *Kähler manifolds*: Michael Wong's 2013 [course notes](#)
- ▷ *cobordism*: Dan Freed's notes [Fre12] and Haynes Miller's notes [Mil]
- ▷ *genera*: Hirzebruch's book [HBJ94]
- ▷ *complex manifolds*: Griffiths and Harris [GH78]

0.3. Acknowledgements. Thank you to Zoë Batterman and Vincent Costa for changes to the notes. Thanks to Sidhanth Raman for helpful correspondence in preparing this class.

1. SHEAVES

The definition of a *sheaf* in Hirzebruch is perhaps a bit different from what we're used to. He wants to think of sheaves as *living over* a space X , whereas we might be comfortable thinking about sheaves as local data across a space. We'll see how these perspectives are equivalent.

Definition 1.1. A *sheaf of abelian groups* over a topological space X is a topological space S with the data of a surjective continuous map $\pi: S \rightarrow X$, for which

- ▷ π is a *local homeomorphism*, meaning for every point $s \in S$ there is an open neighborhood $U \ni s$ for which

$$\pi|_U: U \rightarrow \pi(U)$$

is a homeomorphism

- ▷ for every $x \in X$, the *stalk* $S_x := \pi^{-1}(x)$ has the structure of an *abelian group*

- ▷ the abelian group structure on S_x is *continuous in x* . Precisely, forming inverses in each fiber defines a continuous function:

$$\begin{aligned} S &\rightarrow S \\ s &\mapsto -s, \end{aligned}$$

and if we denote by $S \times_X S$ the subspace

$$S \times_X S := \{(s_1, s_2) \in S \times S : \pi(s_1) = \pi(s_2)\} \subseteq S \times S,$$

then the operation of addition is a continuous function:

$$\begin{aligned} S \times_X S &\rightarrow S \\ ((\alpha, x), (\beta, x)) &\mapsto (\alpha + \beta, x). \end{aligned}$$

We should think about a sheaf of abelian groups as being a space where we can do abelian group operations (addition, subtraction), but where the abelian group in which we're working is *changing* according to the topology of X .

Example 1.2 (Zero sheaf). The identity map $X \rightarrow X$ can be considered a sheaf, where the abelian group structure on each stalk is just the trivial group with one element.

Example 1.3 (Constant sheaves). For any abelian group A and any space X , we get a *constant sheaf*

$$X \times A \rightarrow X,$$

where π is the projection onto X . When $A = \{0\}$, this recovers the zero sheaf above.

Example 1.4 (Skyscraper sheaves). If we want build a sheaf with some *prescribed* fiber A over a point $x \in X$ (we want a name for the map of the inclusion of a point, so let's call it $i: \{x\} \rightarrow X$), we have an nice way to do this – namely, we can take the discrete set underlying the abelian group A , and build the space which we call i_*A , defined as

$$i_*A = \frac{X \times A}{(y, a_1) \sim (y, a_2) \text{ for } y \neq x}.$$

That is, we identify all the points of A together over every point in X *except* our specified point x . We call it a *skyscraper sheaf* because it has this big tall stalk at x and is flat everywhere else. This space comes equipped with a projection back to X which is a continuous local homeomorphism, and the abelian group structure on the stalks over points other than x are just the structure on the one-element group. Note that this resulting space i_*A is very much not Hausdorff.

Example 1.5 (c.f. [Bre97, 1.3]). The *line with doubled origin* is the skyscraper sheaf over \mathbb{R} defined by $i_*(\mathbb{Z}/2)$, where $i: \{0\} \hookrightarrow \mathbb{R}$ is the inclusion of the origin.

Notation 1.6. For any sheaf of abelian groups $\pi: S \rightarrow X$, we have the so-called *zero section* $z: X \rightarrow S$, sending each element $x \in X$ to the zero element in S_x . This map is continuous and has the property that

$$\pi \circ z = \text{id}_X.$$

Exercise 1.7. Let $\pi: X \rightarrow S$ be any sheaf and $z: X \rightarrow S$ the zero section. Then $\text{im}(z) \subseteq S$ is open.

Example 1.8. The projection $\mathbb{R} \rightarrow S^1$ cannot be given the structure of a sheaf of abelian groups.

Proof. We're tempted to say it looks like a sheaf, since each fiber looks like \mathbb{Z} , however it turns out there is no way to endow these fibers simultaneously with the additive structure of the integers.

Suppose towards a contradiction there was. Then composing with the zero section, we get a composite which is the identity:

$$S^1 \xrightarrow{z} \mathbb{R} \xrightarrow{\pi} S^1.$$

Applying π_1 or H_1 for instance, we have that the identity on \mathbb{Z} factors through zero, which is a contradiction. \square

Remark 1.9. Just as we have a sheaf of abelian groups, we can have a sheaf with other structures as well — we could have a sheaf of R -modules for instance. All that's important is that:

- (1) our structure is a set with extra data
- (2) we have that data in every stalk
- (3) the data varies continuously in the stalks

Definition 1.10. A *morphism of sheaves* between $\pi: S \rightarrow X$ and $\tilde{\pi}: \tilde{S} \rightarrow X$ is a continuous map $f: S \rightarrow \tilde{S}$ satisfying the following properties:

▷ $\tilde{\pi} \circ f = \pi$, that is, we have a commutative diagram

$$\begin{array}{ccc} S & \xrightarrow{f} & \tilde{S} \\ \pi \searrow & & \swarrow \tilde{\pi} \\ & X & \end{array}$$

Note this implies that f restricts to a map on each stalk, that is, we get maps $f_x: S_x \rightarrow \tilde{S}_x$ for each $x \in X$

▷ for each $x \in X$, the induced map on stalks

$$f_x: S_x \rightarrow \tilde{S}_x$$

is an abelian group homomorphism.

Exercise 1.11. Show that every morphism between sheaves of abelian groups is a local homeomorphism.

Definition 1.12. We say a morphism of sheaves $f: S \rightarrow \tilde{S}$ is:

- (1) *injective* if each f_x is injective
- (2) *surjective* if each f_x is surjective.

We say a sequence of maps of sheaves

$$S \xrightarrow{f} T \xrightarrow{g} U$$

is *short exact* if $S_x \xrightarrow{f_x} T_x \xrightarrow{g_x} U_x$ is a short exact sequence of abelian groups for every $x \in X$.

1.1. Sheaves and presheaves. Given any sheaf $S \rightarrow X$, we can ask when we have *sections*, which are maps $X \rightarrow S$ that are right inverses to the projection map π .

Definition 1.13. We define the set of *sections* by

$$\Gamma(X, S) := \{s: X \rightarrow S \text{ continuous} \mid \pi \circ s = \text{id}_X\}.$$

Note that $\Gamma(X, S)$ is an abelian group by adding sections pointwise. The zero element of $\Gamma(X, S)$ is the zero section.

Note that we don't need sections to be defined on all of X — we could look at sections defined on subspaces. For instance if $U \subseteq X$ is an open subspace, we can define

$$\Gamma(U, S) := \{s: U \rightarrow S \mid \pi \circ s = \text{id}_U\}.$$

If $V \subseteq U$ is an open subspace, there is a natural *restriction* map

$$\begin{aligned} \text{res}_V^U: \Gamma(U, S) &\rightarrow \Gamma(V, S) \\ s &\mapsto s|_V. \end{aligned}$$

Notation 1.14. For X a topological space, we denote by $\text{Open}(X)$ the category whose objects are open subspaces of X and whose morphisms are inclusions. Then the constructions above tell us that $\Gamma(-, S)$ defines a functor

$$\Gamma(-, S): \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}.$$

This is called the *presheaf* associated to S .

Terminology 1.15. If $S \rightarrow X$ is a sheaf, an element of $\Gamma(X, S)$ will be called a *global section*. This is to indicate it is defined globally, i.e. everywhere on X , in contrast with sections only defined locally on some open subspace U .

Let's think about what structures of S we can recover from its presheaf.

Question 1.16. Can we recover the stalk S_x from the presheaf $\Gamma(-, S)$?

We can't just take Γ and evaluate it on the one-point set $\{x\}$ since this won't be open in most reasonable topological spaces. Instead, we can take elements in $\Gamma(U, S)$ for any $U \ni x$, and glue sections together along restriction of open sets containing x . This is called a *colimit* (in classical terminology, a *direct limit*):

$$\text{colim}_{U \ni x} \Gamma(U, S).$$

Proposition 1.17. For every sheaf of abelian groups $S \rightarrow X$ and every $x \in X$, the canonical “evaluation at x ” map

$$\text{ev}_x: \text{colim}_{U \ni x} \Gamma(U, S) \rightarrow S_x$$

is an isomorphism of abelian groups.

Proof. If $s_1(x) = s_2(x) = a$, then since π is a local homeomorphism, there is some small neighborhood $V \ni a$ on which $\pi|_V: V \rightarrow \pi(V)$ is a local homeomorphism. In particular since $s_1|_{\pi(V)}$ and $s_2|_{\pi(V)}$ are both sections (right inverses) of $\pi|_V$ they must agree. Since they agree on a sufficiently small open neighborhood around x , they agree in the colimit. This establishes injectivity.

To see surjectivity, if $a \in S_x$, we want to create a section s defined in a neighborhood U of x for which $s(x) = a$. We again leverage the fact that π is a local homeomorphism to find some neighborhood $V \ni a$ for which $\pi: V \xrightarrow{\sim} \pi(V)$ is a homeomorphism. Then the inverse to this map satisfies $\pi^{-1}(x) = a$. \square

This gives us an alternative way to look at stalks. Now we know we can recover stalks from the underlying presheaf.

Question 1.18. Can we recover the sheaf S from the presheaf $\Gamma(-, S)$?

That is, suppose someone hands you a functor

$$F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab},$$

and tells you it is of the form $\Gamma(-, S)$ for some sheaf S , but they don't tell you what S is. Can you rebuild S ? Let's denote by

$$F_x := \text{colim}_{U \ni x} F(U)$$

the stalk at a point $x \in X$. Then we know how to construct the sheaf as a *set*, namely it is

$$\coprod_{x \in X} F_x \rightarrow X.$$

The question then becomes how to topologize the thing on the left. Each F_x has the discrete topology as an abelian group, and the disjoint union has the discrete topology a priori – but if we accept this topology, then in general we won't have the property that the projection map is a local homeomorphism. So we need to hunt for a different topological structure. The trick to finding it is that we know how to write down sections, and we want to *force sections to be continuous*.

We denote by

$$\text{germ}_x: F(U) \rightarrow F_x$$

the structure map (part of the data of the colimit) to the stalk (c.f. [Proposition 1.17](#); we called this an evaluation map earlier when we knew $F(U)$ was comprised of actual sections. We don't know that a priori now). For any $s \in F(U)$, we then get a composite

$$\begin{aligned} U &\rightarrow \coprod_x F_x \\ x &\mapsto \text{germ}_x(s). \end{aligned}$$

This should be like a section of the sheaf, so we want it to be continuous. We want the preimage of opens to be open, and since U is indeed open, an easy way to try to force continuity is to ask for the image of this map above to be open.

Definition 1.19. We define a *basis*¹ for a topology on $\coprod_x F_x$ by

$$[(s, U)] := \{\text{germ}_x(s) \mid x \in U\}$$

for any $s \in F(U)$.

It now suffices to verify that this satisfies the axioms for a basis:

B1 *The basis elements cover our space:* Take some $x \in X$ and $a \in F_x$. We want to argue there is a basis element containing it. By the construction of F_x as a colimit of abelian groups, there is some $V \in \text{Open}(X)$ and some $s \in F(V)$ for which $\text{germ}_x(s) = a$. That is, by definition, $a \in [(s, V)]$.

B2 *Common refinement:* Suppose we have $[(s_1, U_1)]$ and $[(s_2, U_2)]$ and $a \in [(s_1, U_1)] \cap [(s_2, U_2)]$. Then we want to find another basis element contained in the intersection of these two and containing a . Let $x = \pi(a)$, then $x \in U_1 \cap U_2$ by definition. So we can look in $F(U_1 \cap U_2)$. By the construction of the colimit, since we have a commutative diagram

$$\begin{array}{ccc} F(U_1) & & \\ & \searrow & \swarrow \\ & F(U_1 \cap U_2) & \xrightarrow{\quad} F_x \\ & \swarrow & \searrow \\ F(U_2) & & \end{array}$$

since $\text{germ}_x(s_1) = \text{germ}_x(s_2)$, their images in $F(U_1 \cap U_2)$ agree. Call that image s . Then we have that

$$a \in [(s, U_1 \cap U_2)] \subseteq [(s_1, U_1)] \cap [(s_2, U_2)] \subseteq \coprod_{x \in X} F_x.$$

So we've checked that we get a basis for a topology.

Remark 1.20. In general, the sheaf $\coprod_{x \in X} F_x$ constructed in this way will be very far from being Hausdorff ([\[Bre97, p. 3\]](#), [\[Ser55\]](#)).

¹See [\[Mun00, II§13\]](#) if this is an unfamiliar term.

It turns out we have in fact built a sheaf! That is, the projection map will be a local homeomorphism.

Lemma 1.21. Let $F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$ be a presheaf, and topologize $\amalg_{x \in X} F_x$ by giving it the basis of [Definition 1.19](#). Then the natural projection

$$\pi: \amalg_{x \in X} F_x \rightarrow X$$

is a local homeomorphism.

Proof. Pick any $a \in F_x$. Then by construction, there exists some open set U and some $s \in F(U)$ so that $\text{germ}_x(s) = a$. In particular, we claim the map

$$\pi|_{[(s,U)]}: [(s,U)] \rightarrow U$$

is a local homeomorphism. It is clearly continuous, and it admits a continuous inverse given by $s: U \rightarrow F(U) \rightarrow [(s,U)]$ by construction. \square

We now have a way to build a sheaf out of a presheaf! So we have a way to go from presheaves to sheaves. I think we've answered [Question 1.18](#), which was if someone hands you a presheaf $F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$, and tells you it is of the form $\Gamma(-, S)$ for some sheaf S , then we can reconstruct S .

Let's now give a slightly different question pandering to a more cynical worldview. Suppose someone hands you a presheaf $F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$ and tells you it is the presheaf of sections attached to some sheaf, but we don't believe them. How might we argue that this cannot come from any sheaf?

Here's an idea of how we might find a way to disagree:

- ▷ if F was of the form $\Gamma(-, S)$ for some S , then $F(U)$ would be equal to $\Gamma(U, S)$
- ▷ we now know how we would reconstruct S : it is $\amalg_{x \in X} F_x$ equipped with the topology defined in [Definition 1.19](#)
- ▷ so we can check: is the canonical map $F(U) \xrightarrow{\theta_U} \Gamma(U, \amalg_{x \in X} F_x)$ a bijection?

Let's recall how this map θ_U worked — each $s \in F(U)$ determines a function $U \rightarrow \amalg_{x \in U} F_x$ given by

$$(1.22) \quad \begin{aligned} \theta_U: F(U) &\rightarrow \Gamma(U, \amalg_{x \in X} F_x) \\ s &\mapsto [x \mapsto \text{germ}_x(s)]. \end{aligned}$$

If θ_U is not a bijection for some open U , then F cannot have come from a sheaf. So let's see when θ_U could fail to be a bijection - that is, when is it injective and when is it surjective? We phrase the following as lemmas, although there's no mathematical content, it's just unwinding definitions.

Lemma 1.23 (When is θ_U a monomorphism?). Let U, θ_U as above. Let's first see what it means for θ_U to send two elements in $F(U)$ to the same thing in $\Gamma(U, \amalg_{x \in X} F_x)$.

- (1) We have that $\theta_U(s) = \theta_U(t)$ if and only if s and t agree locally – that is, for every $x \in U$ there is some open $V \ni x$ for which $s|_V = t|_V$.

This tells us the content of being a monomorphism is that “being equal locally implies you are equal.” In other words:

- (2) θ_U is a monomorphism if and only if, for every $x \in X$, if there is a neighborhood $V \ni x$ with $s|_V = t|_V \in F(V)$, then $s = t$ in $F(U)$.

As the V 's chosen this way form an open cover of U , we can reword this as:

- (3) θ_U is a monomorphism if and only if, for every open cover $\{U_i\}$ of U , if $s, t \in F(U)$ satisfies $s|_{U_i} = t|_{U_i}$ for all i , then $s = t$.

Proof. For the first point, we have that $\theta_U(s) = \theta_U(t)$ if and only if the functions $u \mapsto \text{germ}_u(s)$ and $u \mapsto \text{germ}_u(t)$ agree, that is, only if $\text{germ}_u(s) = \text{germ}_u(t)$ in F_u for all $u \in U$. By construction of F_u

as a colimit, we have that there must exist some neighborhood $V \ni u$ for which $s|_V = t|_V$ in $F(V)$. The second point is a rephrasing of the first, and (3) is a rephrasing of the second point. \square

Lemma 1.24 (When is θ_U an epimorphism?). Let U, θ_U be as above, and suppose Lemma 1.23(3) holds. We want to know when θ_U hits some element $a \in \Gamma(U, \amalg_{x \in X} F_x)$

- (1) Let $a \in \Gamma(U, \amalg_{x \in X} F_x)$. Then for each $x \in U$, we have that $a(x) \in F_x$. By the construction of F_x as a colimit, this means there is some open neighborhood $U_x \ni x$, and some element $s_x \in F(U_x)$ so that, under the structure map $F(U_x) \rightarrow F_x$, we have that $s_x \mapsto a(x)$. Another way to say that is that the section $\theta_{U_x}(s_x)$ agrees with a at the point x . Since π is a local homeomorphism, we have that a and $\theta_{U_x}(s_x)$ must agree on some open neighborhood $V_x \ni x$ which, without loss of generality, we may assume to be a subspace of U_x . So we have that $\theta_{V_x}(s_x) = a|_{V_x}$ and $\theta_{V_y}(s_y) = a|_{V_y}$, so under restriction we get

$$\theta_{V_x \cap V_y}(s_x) = a|_{V_x \cap V_y} = \theta_{V_x \cap V_y}(s_y).$$

If we assumed that the θ 's were injective, Lemma 1.23(3), this says that

$$s_x|_{V_x \cap V_y} = s_y|_{V_x \cap V_y}.$$

And we have that a is in the image of θ_U if and only if there is some $s \in F(U)$ so that $s|_{V_x} = s_x$ for each $x \in U$. In other words, θ_U is surjective if, any time locally defined sections agree on overlaps, there is a section defined on all of U restricting to them.

- (2) With the hypotheses above, we have that θ_U is surjective if and only if, for every cover $\{U_i\}_{i \in I}$ of U , and elements $s_i \in F(U_i)$ satisfying $s_i|_{U_i \cap U_j} = s_j|_{U_i \cap U_j}$, there exists an element $s \in F(U)$ so that $s|_{U_i} = s_i$ for each i .

So what conditions were essential to showing that θ_U was a bijection for every U ? It was Lemma 1.23(3), which tells us if sections agree *locally* then they agree *globally*, and Lemma 1.24(2), which told us that sections defined locally and agreeing on overlaps can be *glued* together to get a global section. These two conditions are called *locality* and *gluing*. Let's summarize our observations:

Theorem 1.25. A presheaf $F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$ is the presheaf of sections attached to a sheaf if and only if the two conditions hold:

Sh1 (Locality) For any open set $U \subseteq X$ and any open cover $\{U_i\}_{i \in I}$ of U , if $s, t \in F(U)$ satisfy $s|_{U_i} = t|_{U_i}$ for each $i \in I$, then $s = t$. Phrased differently, the map

$$F(U) \rightarrow \prod F(U_i)$$

is injective.

Sh2 (Gluing) If $\{U_i\}_{i \in I}$ is an open cover of U , and we have elements $s_i \in F(U_i)$ for each i so that $s_i|_{U_i \cap U_j} = s_j|_{U_i \cap U_j}$ for all i, j , then there exists some $s \in F(U)$ so that $s|_{U_i} = s_i$ for each i . Phrased differently, $F(U)$ surjects onto the equalizer of the parallel restriction maps

$$\prod F(U_i) \rightrightarrows \prod F(U_i \cap U_j).$$

Remark 1.26. Let E denote the equalizer $E = \text{eq}(\prod F(U_i) \rightrightarrows \prod F(U_i \cap U_j))$. By functoriality, the map $F(U) \rightarrow \prod F(U_i)$ factors through E , and $E \rightarrow \prod F(U_i)$ is always a monomorphism. So for presheaves of abelian groups, locality reduces to the statement that $F(U) \rightarrow E$ is injective, while gluing restricts to the statement that $F(U) \rightarrow E$ is surjective. Hence altogether the sheaf condition can be compressed to the assertion that, for any $U \subseteq X$ and any open set $\{U_i\}$ of U , the sequence is an equalizer:

$$F(U) \rightarrow \prod F(U_i) \rightrightarrows \prod F(U_i \cap U_j).$$

Remark 1.27. In an abelian category, an equalizer of two maps $f, g: A \rightrightarrows B$ is the same as the kernel of their difference $A \xrightarrow{f-g} B$. So the locality and gluing conditions can be condensed into the statement that, for every open subspace $U \subseteq X$ and every open cover $\{U_i\}$ of U , the sequence

$$0 \rightarrow F(U) \rightarrow \prod F(U_i) \rightarrow \prod F(U_{ij})$$

is exact, where that rightmost map is the difference of the two restrictions. If we ever want to talk about sheaves of *sets* we can't do this, because subtracting two functions doesn't make sense unless they are group homomorphisms.

Corollary 1.28. There is an isomorphism of categories between

$$\{\text{sheaves on } X\} \simeq \left\{ \begin{array}{c} \text{the full subcategory of presheaves on } X \\ \text{satisfying locality and gluing} \end{array} \right\}.$$

Proof. We have shown a bijection on objects, so it suffices to verify that there is also a bijection on morphisms of each type.

Let S and S' be sheaves. Then a map of sheaves $f: S \rightarrow S'$ clearly induces a map of presheaves, since any section $U \rightarrow S$ can be postcomposed with f to get a section $U \rightarrow S'$, hence we get an induced map $\Gamma(U, S) \rightarrow \Gamma(U, S')$ which is easily seen to be compatible with restriction.

Conversely, suppose we have two presheaves $F, G \in \text{Fun}(\text{Open}(X)^{\text{op}}, \text{Ab})$ which satisfy locality and gluing, and a morphism of presheaves $F \rightarrow G$. We want to see how this induces a morphism of sheaves $\amalg_{x \in X} F_x \rightarrow \amalg_{x \in X} G_x$. We first observe that, by taking colimits, there is a natural induced map on stalks $F_x \rightarrow G_x$ for every X , so we get a commutative diagram of *sets*

$$\begin{array}{ccc} \amalg_{x \in X} F_x & \xrightarrow{f} & \amalg_{x \in X} G_x \\ & \searrow & \swarrow \\ & X. & \end{array}$$

We now want to check that this induced map f is actually continuous. Since we can check continuity on a basis of the target space (reference needed), we can take some $[(t, U)] \subseteq \amalg_{x \in X} G_x$ and try to see its preimage is open in $\amalg_{x \in X} F_x$. We can check that

$$f^{-1}([(t, U)]) = \{\text{germ}_x(s) \mid x \in U \text{ and } \text{germ}_x(f \circ s) = \text{germ}_x(t)\}.$$

Pick one such point $\text{germ}_x(s) \in f^{-1}([(t, U)])$. Since $\text{germ}_x(f \circ s) = \text{germ}_x(t)$, there is some open neighborhood $V \ni x$ for which $(f \circ s)|_V = t|_V$. This means every germ of s over V lies in the preimage of f , that is,

$$\text{germ}_x(s) \in [(s, V)] \subseteq f^{-1}([(t, U)]).$$

In particular this implies that $f^{-1}([(t, U)])$ is open and therefore that f is continuous.

Verifying these two assignments are inverse is immediate by construction in one direction, and is the content of θ_U being bijective in the other direction direction. \square

Remark 1.29 (Important). What we have been calling sheaves (following Hirzebruch, Bredon, Serre) are now more commonly called the *éspace étalé* of a sheaf, while the associated presheaf, satisfying locality and gluing, is what is known contemporarily as a sheaf. The equivalence of categories above tells us it doesn't quite matter which one we talk about, but it's important to keep in mind our definition is technically different than the modern one.

Remark 1.30. The big advantage now is that we can describe a sheaf *in terms of its sections!* We don't even need the sections to form a sheaf, we can always construct a sheaf out of a presheaf if need be.

Example 1.31 (Orientation sheaf). Let M be an n -dimensional manifold, and define a sheaf by the presheaf

$$\begin{aligned} o_M : \text{Open}(M)^{\text{op}} &\rightarrow \text{Ab} \\ U &\mapsto H_n(M, M - U; \mathbb{Z}). \end{aligned}$$

We call this the *orientation sheaf* of M (something to check: relative homology classes satisfy locality and gluing). Then an *orientation* of M is exactly a global section $\omega \in \Gamma(M, o_M)$ with the property that the stalk of ω at each $x \in M$ is a generator of the abelian group $o_{M,x} = H_n(M, M - \{x\}; \mathbb{Z}) \cong \mathbb{Z}$. This is just a rephrasing of [Hat01, pp. 233–236].

Remark 1.32. The étale space of the orientation sheaf is *not* the double cover of M , since this will not be a sheaf of abelian groups, only a sheaf of $\mathbb{Z}/2$ -torsors. The étale space of o_M will have fiber \mathbb{Z} (if we are defining o_M by homology with integral coefficients) and will be the infinite-sheeted cover corresponding to the orientation character $\pi_1(M) \rightarrow \text{Aut}(\mathbb{Z}) = \mathbb{Z}/2$ given by the first Stiefel-Whitney class. We'll learn more about this later on.

1.2. Digression: big and small sites. To briefly tie what we've been doing into the language of Grothendieck topologies, we have the slice category $\text{Top}_{/X}$ of spaces over X , which comes equipped with a Grothendieck topology given by open subsets. We could call $\text{Top}_{/X}$ the *big site*, and in this terminology $\text{Open}(X) \subseteq \text{Top}_{/X}$ is the *small site*, which is the full subcategory on open subsets of X .

1.3. Sheaves of functions. The following is a space-level analogue of the idea that representable presheaves are sheaves.

Example 1.33 (Representable sheaves). Let X and Y be any spaces. Then the assignment

$$\begin{aligned} \text{Open}(X)^{\text{op}} &\rightarrow \text{Set} \\ U &\mapsto \text{Hom}_{\text{Top}}(U, Y) \end{aligned}$$

is a sheaf of sets. We call this the *representable sheaf* attached to Y , although this is maybe a slight abuse of terminology?²

Proof. We just have to verify that the presheaf of functions valued in Y satisfies locality and gluing, which is immediate. \square

Question 1.34. When would this be a sheaf of groups or of abelian groups? That is, when we can endow $\text{Hom}_{\text{Top}}(U, Y)$ with a group structure compatibly for all U . One way to insist on this is to consider $\text{Hom}_{\text{Top}}(-, Y)$ by extending its domain to all of Top , and then ask for it to be valued in groups rather than sets. This is the same data (by the Yoneda lemma) as asking for Y to come equipped with continuous multiplication and inversion maps which turn Y into a group compatibly with its topology. This is the data of being a *topological group*, which we'll define in ??.

Example 1.35. Let X be any space, and denote by

$$\mathbb{C}_c : \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$$

the sheaf sending $U \subseteq X$ to the abelian group of complex-valued continuous functions $U \rightarrow \mathbb{C}$. We call \mathbb{C}_c the *sheaf of germs of local complex-valued continuous functions*, following [Hir78, p. 23].

In general for spaces, we can take a sheaf of continuous functions valued in \mathbb{R} , in \mathbb{C} , in some other space, whatever we like. If X has more structure, we can ask for these functions to respect the additional structure!

²Technically speaking, Y should be viewed as a representable sheaf on $\text{Top} = \text{Top}_{/*}$, which is the big site over the one-point space. We can pull this back along the projection $X \rightarrow *$ and we get a sheaf $\text{Hom}_{\text{Top}_{/X}}(-, X \times Y)$, which, when restricted to the small site $\text{Open}(X)$, agrees with $\text{Hom}_{\text{Top}}(-, Y)$ by adjunction.

Example 1.36. Let X be a differentiable manifold. We denote by \mathbb{C}_b the sheaf of local complex-valued differentiable functions.³

Example 1.37. Let X be a complex manifold. We let \mathbb{C}_ω denote the sheaf of local holomorphic functions.

Exercise 1.38. If X is a compact connected complex manifold, show that $\Gamma(X, \mathbb{C}_\omega) = \mathbb{C}$.

1.4. Sheafification. Let $\text{Ab}(X)$ denote the category of sheaves of abelian groups. It is clearly a full subcategory of $\text{Fun}(\text{Open}(X)^{\text{op}}, \text{Ab})$. Our goal is to show the following:

Theorem 1.39. The category $\text{Ab}(X)$ is a localization of $\text{Fun}(\text{Open}(X)^{\text{op}}, \text{Ab})$, that is, the inclusion admits a left adjoint called *sheafification*. Moreover sheafification preserves stalks.

Our goal is to define the sheafification of a presheaf F over X . We claim we've already seen this construction, it's simply the space $\amalg_{x \in X} F_x \rightarrow X$ we built previously.

Definition 1.40. Let $F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$ be a presheaf. We will define the *sheafification* of F to be the sheaf F^\sharp defined as $\amalg_{x \in X} F_x$, topologized as in [Definition 1.19](#)

Remark 1.41. We can interpret $F^\sharp(U) = \Gamma(U, \amalg_{x \in U} F_x)$ as the set of those tuples $(f_x)_{x \in U} \in \prod_{x \in U} F_x$ for which, for any $x \in U$ there exists an open neighborhood $V \ni x$ and a section $s \in F(V)$ satisfying $s_v = f_v$ for all $v \in V$ (see e.g. [\[Aut, 007X\]](#)).

There is clearly a natural map of presheaves $F \rightarrow F^\sharp$, and we've already seen it! We called it θ_U in [Equation \(1.22\)](#). It induces an isomorphism on stalks by definition. The thing to check is that the sheafification construction is functorial (omitted) and defines a left adjoint to the inclusion of sheaves in presheaves. Adjunction follows from the following universal property:

Proposition 1.42. Let $F \in \text{Fun}(\text{Open}(X)^{\text{op}}, \text{Ab})$ and $G \in \text{Ab}(X)$. Then any map $F \rightarrow G$ factors uniquely through F^\sharp .

Proof. By construction there is a commutative diagram

$$\begin{array}{ccc} F & \longrightarrow & F^\sharp \\ \downarrow & & \downarrow \\ G & \longrightarrow & G^\sharp, \end{array}$$

so it suffices to check that $G \rightarrow G^\sharp$ is an equivalence of sheaves, but this is true because it is a stalkwise isomorphism.⁴ \square

1.5. Subsheaves and cokernels.

Notation 1.43. For a topological space X , we denote by $\text{Ab}(X)$ the category of *sheaves of abelian groups* on X , and morphisms between them. Again following the equivalence of categories of [Corollary 1.28](#) we're allowed to work with local homeomorphisms of abelian groups over X or presheaves on X satisfying the sheaf condition. So every definition and statement we make here will have two equivalent formulations in each model of sheaves. We will provide both at the start but will begin dropping one for convenience as we continue.

Definition 1.44 (Subsheaf). Let $F: \text{Open}(X)^{\text{op}} \rightarrow \text{Ab}$ be a sheaf. We say that a sheaf G is a *subsheaf* of F if $G(U) \leq F(U)$ is a subgroup for each $U \in \text{Open}(X)$, and for any $V \subseteq U$, the restriction map $\text{res}_U^V: F(U) \rightarrow F(V)$ is equal to the restriction map $G(U) \rightarrow G(V)$ for G .

³Recall a complex-valued function is differentiable if and only if both its real and imaginary parts are.

⁴This wouldn't work if G was just a presheaf, as although $G \rightarrow G^\sharp$ is a stalkwise isomorphism that does not imply it is an isomorphism of presheaves, only of sheaves.

Definition 1.45 (Subsheaf, éspace étalé model). We say that a sheaf $\pi_1: S_1 \rightarrow X$ is a *subsheaf* of $\pi_2: S_2 \rightarrow X$ if

- (1) $S_1 \subseteq S_2$ is an open subspace
- (2) $\pi_1 = \pi_2|_{S_1}$
- (3) The stalk $(S_1)_x$ is a subgroup of the stalk $(S_2)_x$ for all $x \in X$.

Just as subgroups of abelian groups are kernels of group homomorphisms, we can construct subsheaves as kernels of abelian sheaf homomorphisms.

Proposition 1.46. If $f: A \rightarrow B$ is a morphism of sheaves over X , we denote by $\ker(f)$ the *kernel*, defined to be the sheaf of A consisting of those points $a \in A$ so that $f_{\pi(a)}(a) = 0$ in $B_{\pi(a)}$.

Proof. We have to verify this is a subsheaf. Let K denote the kernel of f , and let's write out the diagram so we can picture it:

$$\begin{array}{ccccc} K & \longrightarrow & A & \xrightarrow{f} & B \\ & \searrow \pi_K & \downarrow \pi_A & \swarrow \pi_B & \\ & & X. & & \end{array}$$

It is clear that π_K is just π_A restricted to K by construction, and moreover the stalks K_x are subgroups of A_x , again by construction. So the only thing to verify is that $K \subseteq A$ is an open subspace. To see this, we note that the kernel of f is the preimage of zero in B , which is the image of the zero section $z_B: X \rightarrow B$. This is open in B by [Exercise 1.7](#), and $K = f^{-1}(\text{im}(z_B))$, which will also be open since f is continuous. \square

Exercise 1.47.

- (1) Let $f: S_1 \rightarrow S_2$ be a morphism of sheaves over X . Give a reasonable definition of an *image* subsheaf $\text{im}(f) \subseteq S_2$.
- (2) Give a reasonable definition of a *cokernel* sheaf $\text{coker}(f)$ over f .
- (3) Prove an analogue of the first isomorphism theorem for sheaves of abelian groups over spaces.
- (4) How does your first iso theorem look on stalks? (c.f. [Definition 1.12](#))

This allows us to find *exact sequences* of sheaves.

Example 1.48. Let \mathbb{C}_c^* be the sheaf of germs of locally never zero complex valued continuous functions. There is a morphism of sheaves \exp , defined on sections by

$$\begin{aligned} \mathbb{C}_c(U) &\rightarrow \mathbb{C}_c^*(U) \\ f &\mapsto \exp(2\pi i \cdot f). \end{aligned}$$

The kernel of this is isomorphic to the constant sheaf \mathbb{Z} , because f and $f + n$ map to the same thing for any $n \in \mathbb{Z}$. We claim that we get a short exact sequence of sheaves

$$0 \rightarrow \mathbb{Z} \rightarrow \mathbb{C}_c \xrightarrow{\exp} \mathbb{C}_c^* \rightarrow 0.$$

The fact that exponentiation is an epimorphism of sheaves is a stalkwise condition, saying that for every value $x \in X$, we can find a sufficiently small neighborhood in which we can take a branch and define $\log(z)$.

APPENDIX A. POINT-SET TOPOLOGY

Definition A.1. A *paracompact space* is a space for which every open cover admits an open refinement which is *locally finite* (each point in the space intersects only most finitely many of the spaces in the refinement).

This is strictly weaker than being compact, since compactness requires the entire cover to be finite, not just locally finite.

Example A.2. Euclidean space \mathbb{R}^n is paracompact but not compact.

Theorem A.3 (Dieudonné, [Hir78, 2.8.2]). Every locally compact space with a countable basis is paracompact.

A.1. Normal spaces. The idea of a *normal* space can be thought of (loosely) as a strengthening of the Hausdorff condition. On T_1 -spaces (spaces in which singletons are closed) this is a literal strengthening of the Hausdorff condition – it says that not only can *points* be separated by open neighborhoods, actually any disjoint *closed subspaces* can be separated by open neighborhoods.

Definition A.4. A space is *normal* if any two disjoint closed subsets can be separated by disjoint open neighborhoods. Explicitly if $Z_1, Z_2 \subseteq X$ are each closed and $Z_1 \cap Z_2 = \emptyset$, then there exist open subspaces $U_1 \supseteq Z_1$ and $U_2 \supseteq Z_2$ so that $U_1 \cap U_2 = \emptyset$.

Theorem A.5 (Dieudonné, [Hir78, 2.8.1]). Every paracompact space is *normal*.

In particular since our manifolds are Hausdorff with countable bases, they are in particular normal.

Lemma A.6 (Urysohn's lemma). A space X is normal if and only if, for every two disjoint closed subsets $A, B \subseteq X$, there exists a continuous function

$$f: X \rightarrow [0, 1]$$

so that $f(A) = 0$ and $f(B) = 1$.

The following crucial result implies that, over a normal space, locally finite covers can always be “shrunk.” It is a crucial ingredient for the existence of partitions of unity.

Theorem A.7 (Shrinking theorem, [Hir78, 2.8.3]). Let X be normal, and $\{U_i\}_{i \in I}$ a locally finite⁵ cover. Then X admits an open cover $\{\bar{V}_i\}_{i \in I}$, indexed over the same set, so that $\bar{V}_i \subseteq U_i$.

Definition A.8. Let $\{U_i\}_{i \in I}$ be an open cover of a space X . We say that a system of continuous functions $\{\phi_i: X \rightarrow \mathbb{R}\}_{i \in I}$ is a *partition of unity subordinate to* the cover if:

- (1) $\phi_i(x) \geq 0$ for all $x \in X$
- (2) $\text{supp}(\phi_i) \subseteq U_i$
- (3) Each point has an open neighborhood meeting $\text{supp}(\phi_i)$ for only finitely many $i \in I$
- (4) We have that

$$\sum_{i \in I} \phi_i(x) = x$$

for all $x \in X$. Note that sum is defined because of the previous point.

Definition A.9. We say an open cover of a space is *numerable* if it admits a subordinate partition of unity. We say a fiber bundle is *numerable* if the base admits a numerable cover over which the total space is trivialized [Dol63, 7.1].

Theorem A.10. A space is paracompact if and only if it is Hausdorff and every open cover admits a partition of unity.

⁵Hirzebruch says *point finite*.

Proof. For a proof see [Hir78, pp. 30–31]. \square

The following result is originally due to Stone? An elegant reproof is due to Mary Ellen Rudin in the 60's. We can find the following in [Mun00, 41.4], for instance.

Theorem A.11. Every metric space is paracompact.

Another crucial example is that CW complexes are paracompact. Miyazaki, Dugundji, Bourgin all separately proved in 1952 that simplicial complexes were paracompact. Miyazaki shortly thereafter extended this result to all CW complexes

Theorem A.12 ([Miy52]). Every CW complex is paracompact.

Sketch. There's a nice outline on the nLab – we can induct on the skeleton, leveraging that disks and spheres are paracompact, and that paracompact Hausdorff spaces are closed under coproducts and pushouts along closed embeddings. \square

APPENDIX B. CATEGORY THEORY

If you are unfamiliar with colimits I really recommend reading Chapter 3 of [Rie16].

B.1. Filtered colimits.

Definition B.1. A category is *filtered* if every finite diagram admits a cocone. Dually a category \mathcal{C} is *cofiltered* if every finite diagram admits a cone.

Example B.2. The category $\text{Open}(X)$ is cofiltered.

Proof. We don't have to worry about morphisms commuting, so it suffices to see, for finitely many $U_1, \dots, U_n \in \text{Open}(X)$, there is a U mapping to them. Clearly we can take $U = U_1 \cap \dots \cap U_n$. \square

Example B.3. For $x \in X$, the category of open subspaces of X containing x is cofiltered.

Definition B.4. Let X be a space, and let $\mathcal{U} = \{U_i\}_{i \in I}$ and $\{V_j\}_{j \in J}$ be two open covers of X . We say that \mathcal{V} is a *refinement* of \mathcal{U} if for every $V \in \mathcal{V}$ there exists some $U \in \mathcal{U}$ so that $V \subseteq U$.

Definition B.5. Let X be a topological space. We denote by $\text{Cov}(X)$ the poset (category) of open covers of X under refinement. That is, an object of $\text{Cov}(X)$ is an open cover \mathcal{U} of X , and for any two covers $\mathcal{U}, \mathcal{V} \in \text{Cov}(X)$, we have exactly one morphism $\mathcal{V} \rightarrow \mathcal{U}$ if \mathcal{V} refines \mathcal{U} , otherwise there are no morphisms from \mathcal{V} to \mathcal{U} .

Example B.6. We have that $\text{Cov}(X)$ is cofiltered. This is precisely the assertion that two covers admit a common refinement, and therefore by induction finitely many covers admit a common refinement.

The important thing about filtered categories is that colimits computed over them are very well behaved.

Proposition B.7. Filtered colimits valued in Set or Ab or any other reasonable concrete category (see [here](#) for details for instance) commute with finite limits.

Corollary B.8. Filtered colimits (valued in Ab, let's say) preserve monomorphisms.

Proof. The property of a morphism $f: x \rightarrow y$ being a monomorphism is equivalent to the statement that the diagram

$$\begin{array}{ccc} x & \xrightarrow{\text{id}} & x \\ \downarrow \lrcorner \quad \downarrow f & & \\ x & \xrightarrow{f} & y \end{array}$$

is a pullback. This is a finite limit, hence commutes with filtered colimits. \square

An interesting question in the setting of abelian categories is the interaction between exactness and filtered colimits. Indeed exactness of filtered colimits is a consequence of Grothendieck's axiom AB5 for abelian categories [Gro57, 1.8.1].

Corollary B.9. Let \mathcal{A} be an abelian category, and let $\text{Fun}^{\text{ex}}(\mathcal{A}, \text{Ab})$ be the full subcategory of exact functors from \mathcal{A} to abelian groups. Then $\text{Fun}^{\text{ex}}(\mathcal{A}, \text{Ab})$ is preserved under filtered colimits.

Proof. Filtered colimits in this category are computed levelwise, hence they commute with finite limits. Being right exact is a colimit, hence commutes with (filtered) colimits in any context. Being left exact is a pullback condition, hence a finite limit, and therefore commutes with filtered colimits. \square

As a remark, this is not true if the colimits are not filtered, as illustrated by the following example:

Example B.10. Let $F = \text{id}_{\text{Ab}}: \text{Ab} \rightarrow \text{Ab}$ be the (clearly exact) identity functor on the category of abelian groups, and consider the (non-filtered!) equalizer diagram

$$0, 2: F \rightrightarrows F,$$

where 0 is the natural transformation given levelwise by the zero homomorphism, and 2 is multiplication by 2. Then we have that the colimit of this diagram is computed by the pointwise coequalizer of 0 and 2. In particular if $C: \text{Ab} \rightarrow \text{Ab}$ is the colimit of the above diagram, then

$$C(A) = A/2A$$

for every abelian group A . But this is not an exact functor $\text{Ab} \rightarrow \text{Ab}$.

We leverage Corollary B.9 a handful of times in the notes. It is important to see when categories are (co)filtered, since this will be useful. A very obvious example is the category $\text{Open}(X)$, which is cofiltered, hence $\text{Open}(X)^{\text{op}}$ is filtered.

B.2. Cofinality.

Definition B.11. Let J be a category, and $I \subseteq J$ a subcategory. We say $I \subset J$ is *cofinal* if, for any functor $F: J \rightarrow \mathcal{C}$, the induced map on colimits

$$\text{colim}_I F \rightarrow \text{colim}_J F$$

is an isomorphism in \mathcal{C} . We say $I \subseteq J$ is *final* if $I^{\text{op}} \subseteq J^{\text{op}}$ is cofinal.

The key reductive step of the Poincaré lemma relies on a recognition of cofinality (really finality, but the category gets “opped” when we take a contravariant functor out of it):

Proposition B.12. Let M be an n -dimensional manifold and let $x \in M$ be an arbitrary point. Then the category of open sets of M containing x admits a final system given by those open sets $U \subseteq M$ so that $U \ni x$ and U is homeomorphic to \mathbb{R}^n .

Proof. Fix a chart (U_0, ϕ) around x . For any $V \ni x$ open, we can intersect it with the chart to get $V \cap U_0$. In the image $\phi(V \cap U_0)$ we can find some open ball containing $\phi(x)$, and the preimage of this in M is both homeomorphic to \mathbb{R}^n and contained in V . \square

The following result is a categorical rephrasing of an important result in differential topology. Before we can phrase it we need a definition.

Definition B.13. Let \mathcal{U} be an open cover of X . We say that it is a *good cover* if all the $U \in \mathcal{U}$ and all the nonempty intersections of finitely many elements in \mathcal{U} are contractible spaces.

Proposition B.14. Let M be a Riemannian manifold, and denote by $\text{Cov}^{\text{good}}(M)$ the category of good open covers of M . Then $\text{Cov}^{\text{good}}(M) \subseteq \text{Cov}(M)$ is a final subcategory.

Proof. The content of this is showing every cover refines to a good one. Fix a cover \mathcal{U} of M , and now pick any point $x \in M$, and any $U \ni x$. Since every point on a Riemannian manifold admits a positive convexity radius, we can obtain a geodesically convex neighborhood around each point, and by potentially shrinking the radius we may assume it is contained in U . This is clearly convex, and it yields a good cover since the intersection of geodesically convex spaces is geodesically convex, hence contractible. \square

In particular, any colimiting construction we want to pursue over covers of a Riemannian manifold can be reduced to good open covers.
